PROBLEM 15

Answer:

1. Assume q is inside P. We want to find the closest point to q in $\{p_1, \ldots, p_n\}$. Reasoning:

Hard and required $\Omega(n)$ runtime. Arrange all points on the circumference of a circle like regular convex n-polygon enclosing point q as its center. If the algorithm is deterministic and assumes an easy case, some points remain unvisited. For those unvisited point, we one of them closer. Therefore, the algorithm can not find the correct closest point and outputting incorrect results.

2. Assume q is outside P. We want to find the closest point to q in $\{p_1, \ldots, p_n\}$. Reasoning:

Hard and required $\Omega(n)$ runtime. Place all points on a quarter-circle like regular convex n-polygon enclosing point q while ensuring P is convex and non-enclosing. Assume easy, then there will be some point that the algorithm (deterministic) will not visit. For an unvisited point, we move it closer. Therefore, the algorithm can not find the correct closest point and outputting incorrect results.

3. Assume q is inside P. We want to find the farthest point to q in $\{p_1, \ldots, p_n\}$. Reasoning:

Hard and required $\Omega(n)$ runtime. Similar to Q1, but this time we move an unvisited point further.

4. Assume q is outside P. We want to find the farthest point to q in $\{p_1, \ldots, p_n\}$.

Reasoning:

Hard and required $\Omega(n)$ runtime. Similar to Q2, but this time we move an unvisited point further.

5. Assume q is inside P. We want to find the closest point to q on P. Reasoning:

Hard and required $\Omega(n)$ runtime. Similar to Q1 again, The number of edges equals the number of points, so we still need at least O(n) runtime.

6. Assume q is outside P. We want to find the closest point to q on P. Reasoning:

Easy and can be solved within O(log n).

The algorithm finds the closest point to q on a convex polygon P in $O(\log n)$ time using the unimodal nature of the distance function from q to P. Using ternary search on the edges of P, it narrows the search interval until the closest edge is identified, and then computes the closest point on that edge. The convexity of P ensures the unimodal property, guaranteeing the correctness of the ternary search.

```
def closest_point_on_convex_polygon(q, P):
    n = len(P)
    low = 0
    high = n - 1
while high - low > 3:
    m1 = low + (high - low) // 3
    m2 = high - (high - low) // 3
    D_m1 = distance_to_edge(q, P[m1], P[(m1 + 1) % n])
    D_m2 = distance_to_edge(q, P[m2], P[(m2 + 1) % n])
    if D_m1 < D_m2:
        high = m2
    else:
        low = m1
min_dist = float('inf')
closest_point = None
for i in range(low, high + 1):
    p1 = P[i]
    p2 = P[(i + 1) \% n]
    c = closest_point_on_segment(q, p1, p2)
    D = distance(q, c)
    if D < min_dist:</pre>
        min_dist = D
        closest_point = c
return closest_point
```

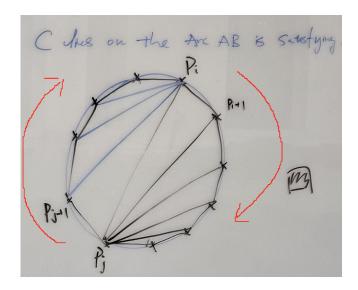

7. Assume q is inside P. We want to find the farthest point to q on P. Reasoning:

Hard and required $\Omega(n)$ runtime. Similar to Q3, so similar argument can be made.

8. Assume q is outside P. We want to find the farthest point to q on P. Reasoning:

Hard and required $\Omega(n)$ runtime. Similar to Q4. The farthest point must lie on the circumcircle as all other points are on an n-gon, so similar argument can be made.

PROBLEM 16

Proof. Let $\{P_1, \ldots, P_n\}$ be the collection of points of a convex polygon P. Steps for Triangulation:

- 1. Order points in clock-wise order $\{p_1,...,p_n\}$.
- 2. Pick the longest side from diagonal or side of $P: P_i, P_i$.
- 3. Pick the third point P_k such that P_k is the neighbor of point p_i OR p_j . WLOG, pick the neighbor of p_i as the third point. We denote the third point as P_{i+1} or P_{j-1} . Note: This P_k is on the opposite arc from P_iP_j .
- 4. Form the first triangle as $\triangle P_i P_j P_k$:
 - (a) Then we iteratively add the rest of the polygon of the "half" of the polygon as:

Note: The neighbor of P_{i+n} is P_{i-1} and P_{i-3} .

$$P_{j}P_{j+1}P_{j+2},\ldots,P_{j}P_{i+n}P_{j-1}$$

(b) For the rest of the "half" of the polygon:

Note: The neighbor of P_{j+m} is P_{i-1} and P_{i-3} .

$$P_iP_jP_{j+1},\ldots,P_iP_{j+m}P_{i-1}.$$

PROBLEM 17

The algorithm identifies all "good" points by first constructing the Voronoi diagram of the given points, which efficiently captures proximity relationships in $O(n \log n)$ time. For each point p_i , it examines only its neighboring points in the Voronoi diagram, as these are the only ones that could potentially interfere with placing a new circle. By computing the angular intervals where a circle of radius ℓ touching C_i would intersect any neighboring C_j , the algorithm determines the directions that are blocked. If there exists at least one direction where such interference does not occur, the point p_i is therefore "good".

```
# Helper Functions
def compute_interfering_angles(p_i, p_j, r, l, d_ij):
    # Calculate the angle between p_i and p_j
    delta_x = p_j.x - p_i.x
    delta_y = p_j.y - p_i.y
    alpha = atan2(delta_y, delta_x)
    # Law of Cosines to find the angular width
    cos_{theta} = (d_{ij}**2 + (r + 1)**2 - (r + 1)**2) / (2 * d_{ij} * (r + 1))
    if abs(cos_theta) <= 1:</pre>
        theta = acos(cos_theta)
        # The interfering interval is [alpha - theta, alpha + theta]
        interval = [(alpha - theta) \% (2 * pi), (alpha + theta) \% (2 * pi)]
        # Handle interval wrapping around 2pi
        if interval[0] > interval[1]:
            return [(interval[0], 2 * pi), (0, interval[1])]
        else:
            return [interval]
    else:
        # Circles do not intersect; no interfering angles
        return []
# Main Function
def find_good_points(P, r, 1):
    # Construct the Voronoi diagram
    # Need O(nlogn)
    V = voronoi_diagram(P)
    good_points = []
    # For each point p_i
    # Need O(n)
    for p_i in P:
        interfering_angles = [] # List to store interfering angular intervals
        # Get neighboring points in the Voronoi diagram
```

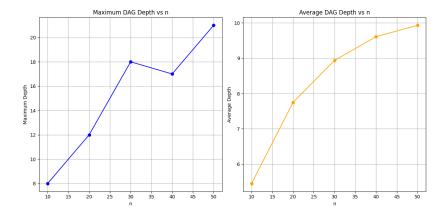

```
neighbors = V.get_neighbors(p_i)
    # For each neighbor p_j
    for p_j in neighbors:
       d_ij = distance(p_i, p_j)
        # Only consider neighbors that may interfere
       if d_{ij} < 2 * (r + 1):
            # Compute the angular intervals of interference
            angles = compute_interfering_angles(p_i, p_j, r, 1, d_ij)
            interfering_angles.extend(angles)
    # Compute the union of interfering intervals
    interfering_union = union_of_intervals(interfering_angles)
    # Determine the complement of the union over [0, 2pi)
   non_interfering_angles = complement_of_intervals(interfering_union, 0, 2 * pi)
    # If there is at least one non-interfering angle, p_i is good
    if non_interfering_angles:
       good_points.append(p_i)
return good_points
```

PROBLEM 18

Result:

$\overline{\textbf{Processing } n}$	Max Depth	Avg Depth
10	8	5.45273631840796
20	12	7.750312109862672
30	18	8.939478067740144
40	17	9.610121836925961
50	21	9.93361327734453

Table 1: Depth statistics for different values of n

Short Analysis:

The result I got is reasonable, with the average depths increasing in *logn* as expected, indicating that the algorithm effectively maintains a balanced DAG structure. Although the maximum depths are somewhat higher than theoretical predictions, they remain within an acceptable range considering the algorithm's randomness and the potential for local depth increases during edge legalization.

Implementation:

The following code of randomized Delaunay triangulation algorithm with history DAG was implemented in Python:

Data Structures Definitions

```
